(Dated: July 25, 2008)

Using first-principle simulations for the probability density of finding a ^3He atom in the vicinity of the screw dislocation in solid ^4He , we determine the binding energy to the dislocation nucleus $E_B = 0.8 \pm 0.1\text{K}$ and the density of localized states at larger distances. The specific heat due to ^3He features a peak similar to the one observed in recent experiments, and our model can also account for the observed increase in shear modulus at low temperature. We further discuss the role of ^3He in the picture of superfluid defects.

PACS numbers: 67.80.-s, 05.30.Jp, 67.30.hm, 61.72.Lk

The observation of a non-classical moment of rotational inertia (NCRI) in torsional oscillator experiments [1] in solid ^4He has revived the debate on superfluids, but its understanding proved to be challenging. Several groups over the world have confirmed NCRI, but aspects such as the pressure dependence [1, 2], disorder [3, 4], history dependence (hysteresis) [5, 6], "critical" velocity [1, 5], crystal growth [3], oscillation frequency [5], rim velocity, and ^3He concentration [7] all show unexpected behavior and defy any simple physical picture (for a review, see [3, 8]). Theoretically, consensus is growing towards a network of superfluid defects as the mechanism of superflow, but some effects cannot yet be explained properly, especially at the quantitative level [9].

One of the main puzzles is the effect of even minute ^3He concentrations. There is mounting evidence that the interplay between ^3He impurities and crystallographic defects (dislocations in single crystals) is not innocuous and can, in fact, be understood theoretically to a large degree. In this Letter, we investigate this topic and focus on the ^3He binding to screw dislocations, which are common crystal defects in solid ^4He .

Day and Beamish observed an increase in the shear modulus of the ^4He crystal when the temperature is lowered [10], which could be understood from binding of ^3He to dislocations at low temperatures. According to the Granato-Lücke theory [11], dislocations move in response to shear stress in their glide plane. More precisely, they bow out between pinning centers provided by impurities or intersections, which can reduce the shear modulus by 30% from its intrinsic value in a frequency independent way. When ^3He binds to a dislocation, it acts as an additional pinning center. Since the change in shear modulus is quadratic in the length between the pinning centers, the shear modulus quickly recovers its intrinsic value. Remarkably, the shear modulus dependence on temperature is nearly identical to that of NCRI. Yet, the two phenomena are distinct: the NCRI signal can not be fully accounted for by the elasticity effect, nor can the

reduction in NCRI by a factor of 100 when blocking an annulus be explained by elasticity arguments [1, 9].

In the torsional oscillator experiments by Kim *et al.* [7] a minimum ^3He concentration of the order of $x_3 \sim 1\text{ppb}$ seems needed in order to observe NCRI. Then, NCRI increases until $x_3 \sim 1\text{ppm}$ where a maximum is reached and finally disappears again for concentrations of about 100ppm. Specific heat measurements showed a nearly constant term in the specific heat at low temperatures scaling with the ^3He concentration [12]. After subtraction of the phonon contribution and the mysterious constant term, a peak in the specific heat was found around $T = 0.06\text{K}$, which was claimed to be independent of x_3 and indicative of the supersolid transition [12] (see however [13]). In this Letter we show, however, that binding of ^3He impurities to dislocations results in a specific heat peak in the same temperature range.

Our approach is numerical and based on Feynman's path-integral formulation of quantum mechanics. The integrals over the paths (world lines) are efficiently evaluated by the worm algorithm [14], which has been successful in describing properties of crystallographic defects in solid ^4He [15, 16, 17, 18]. We now describe how the method needs to be modified in order to deal with ^3He impurities.

The grand partition function $Z = \text{Tr } e^{-\beta(\hat{H}-\mu\hat{N})}$ is expressed as a path integral with the usual discretization of the imaginary time (inverse temperature) β into M slices ($\delta = \beta/M$),

$$Z \approx \sum_{N=0}^{\infty} e^{\beta\mu N} \int d\mathbf{R} T(\mathbf{R}) e^{-\delta U(\mathbf{R})}, \quad (1)$$

where $\mathbf{R} = (R_0, R_1, \dots, R_M = PR_0)$ is a particular world-line configuration with $R_j = \{\mathbf{r}_{1,j}, \mathbf{r}_{2,j}, \dots, \mathbf{r}_{N,j}\}$ the coordinates of all N particles in time slice j , and $d\mathbf{R} = dR_0 \dots dR_{M-1}$. All permutations P of the bosons are incorporated in the periodic boundary condition $R_M = PR_0$. We use the primitive approximation [19] where $U(\mathbf{R})$ contains only the inter-particle interaction

FIG. 1: (Color online) Reweighting function (line) and mass histogram (bars) as a function of ratio between the impurity particle mass and the ^4He mass.

given by the Aziz potential [20]. The kinetic term $T(\mathbf{R})$ is a product of free-particle propagators [19],

$$T(\mathbf{R}) = \prod_{k=1}^N \prod_{j=0}^{M-1} (4\pi\lambda^{(k)}\delta)^{-3/2} e^{-\frac{(\mathbf{r}_{k,j+1} - \mathbf{r}_{k,j})^2}{4\lambda^{(k)}\delta}}, \quad (2)$$

where $\lambda^{(k)} = \hbar^2/(2m^{(k)})$ depends on the mass of particle k [25].

We cannot just add a substitutional ^3He atom to the setup and wait for it to hop around, because the exchange amplitude between ^4He and ^3He atoms is very small in solid ^4He , $J_{34} \sim 10^{-4}\text{K}$ [21] compared to the temperatures of interest ($T \sim 0.5\text{K}$). A partial solution to this problem is to allow for a special Monte Carlo update, which relabels ^3He and ^4He trajectories (a ^4He trajectory which is not part of any exchange cycle is chosen at random) thus leaving the world line configuration unchanged. As both ^4He and ^3He interact via the same potential, only the kinetic part in Eq. (1) is affected by this update. Using Eq. (2), the acceptance probability is

$$p_{ex} = \frac{T_{\text{new}}}{T} = \min\{1, e^{-(l_3 - l_4)(m_4 - m_3)/\delta}\}, \quad (3)$$

with $l_i = \sum_{j=0}^{M-1} (\mathbf{r}_{k_i,j+1} - \mathbf{r}_{k_i,j})^2 \hbar^2/2$ and m_i the mass, where the index $i = 3, 4$ refers to the ^3He and ^4He particle of the current update, respectively. Typical acceptance ratios are of the order of 10^{-7} and thus prohibitively low. The problem is that the ^3He trajectory has a bigger fluctuation volume than the ^4He one.

To overcome this problem we introduce an update which gradually changes the mass m of an impurity particle over the interval $[m_3, m_4]$. We do not allow for more than one impurity atom and work with a discrete set of 11 impurity masses $m = m_3 + \Delta m * i$ where $i = 0, 1, \dots, 10$ and $\Delta m = (m_4 - m_3)/10$. A gradual change in mass allows the crystal to relax and readjust the configuration to the new impurity mass. If m is close or equal to m_4 , the

FIG. 2: (Color online) The probability density of finding a single ^3He atom at a radial distance r (cylindrical coordinates) from the core of the screw dislocation for different temperatures. Errors are indicated by the dashed lines for $T = 0.5\text{K}$, and are of the same order at higher temperatures. The grey line shows the reference for ^4He in the absence of an impurity. The density is $n = 0.0295\text{\AA}^{-3}$. At large distances, $r > 30\text{\AA}$ ($r > 25\text{\AA}$ for $T \geq 1\text{K}$), the ^4He atoms are treated as inert particles (with fixed straight world lines) and form a zone inaccessible to the impurity atom.

exchange updates are frequently accepted. The quantities of interest are only measured in the "physical" sector, where $m = m_3$. The acceptance probability for changing the mass from m to $m \pm \Delta m$ is

$$p_{m \rightarrow m \pm \Delta m} = \min\{1, (1 \pm \Delta m/m)^{3M/2} e^{-l_3 \Delta m/\delta}\}. \quad (4)$$

This in itself does not solve the problem, since on average $p_{m \rightarrow m - \Delta m} < 1$ and we only rarely visit the low-mass sector of the configuration space. The final solution is in employing a reweighting (importance sampling) technique which ensures that the probability of visiting different mass sectors are approximately equal. This is achieved by introducing the reweighting function $g(m)$ shown in Fig. 1 into the acceptance probability

$$p_{m \rightarrow m \pm \Delta m} \rightarrow p_{m \rightarrow m \pm \Delta m} g(m)/g(m \pm \Delta m). \quad (5)$$

This enables the impurity to efficiently sweep over the entire mass range. Every time the impurity is a true ^3He atom, we measure its distance r to the nucleus of the screw dislocations and update the histogram for the radial probability density $g(r)$ shown in Fig. 2.

Relating $g(r)$ to the effective potential energy $E(r)$ between a ^3He atom and the dislocation core is straightforward. The exchange matrix element between ^3He and ^4He is negligible ($\sim 10^{-4}\text{K}$) compared to the temperatures of interest ($T > 20\text{ mK}$) and can be ignored altogether, leaving us with the classical Boltzmann distribution $g(r) \propto \exp[-\beta E(r)]$. At large distances we assume $E(r) \propto r^{-2}$ from elasticity theory [22] and proceed as follows: first we fit the tail of $g(r)$ to

FIG. 3: (Color online) Specific heat as a function of temperature for a single ^3He impurity in the strain field of a screw dislocation obtained directly from the $g(r)$ curve at $T = 0.5\text{K}$ in Fig. 2 and assuming $x_d = 10^6/a^2 = 7.6 \times 10^8 \text{ cm}^{-2}$. The specific heat is exponentially suppressed at temperatures well above where the maximum is reached. The dashed lines correspond to the errors coming from the error on $g(r)$ in Fig. 2. The specific heat curves resulting from $g(r)$ at higher temperatures ($T = 1\text{K}$ and $T = 1.5\text{K}$ in Fig. 2) are the same as the one shown, within error bars.

$g_\infty \exp(-\beta B/r^2)$ law to determine the asymptotic behavior (g_∞ and B are fit parameters), and then we obtain the potential energies from $E(r) = -T \ln[g(r)/g_\infty]$ for distances $r < 20\text{\AA}$. The partition function is found by integrating $\exp[-\beta E(r)]$ over all lattice sites up to some cut-off value $r_{\text{max}} = 1/\sqrt{\pi x_d}$ where x_d is the dislocation density per a^2 and a the inter-particle distance. The specific heat c_V shown in Fig. 3, is directly calculated from $g(r)$ shown in Fig. 2 with only x_d as a free parameter. The partition function can be written approximately as $Z \approx 1/x_d + N_B \exp(\beta E_B)$ where N_B is the number of the deepest binding sites (with energy $-E_B \approx -T \ln[g_{\text{max}}/g_\infty] = 0.8 \pm 0.1\text{K}$) per lattice period.

The specific heat maximum is roughly at $T_{\text{max}} \approx E_B / \ln[1/(N_B x_d)]$ with only a logarithmic dependence on the free parameter x_d . The peak falls in the same temperature range as the peak of Ref. [12]. The peak amplitude scales with the ^3He concentration (since the Pauli exclusion can be neglected for low x_3 and assuming full equilibration) and has the typical shape of a Schottky peak for a system with two degenerate energy levels (see above). Further refinements of our model, such as working with discrete lattice points close to the core, using a Fermi function, or a distribution of binding energies for different dislocation types, are possible, but do not seem needed.

The Shevchenko state of the network of interconnected superfluid dislocations [17, 23] predicts a crossover in the specific heat from $c_V \propto T$ above the bulk transition temperature T_c to $c_V \propto T^3$ at low temperatures $T < T_c$. This signal, however, might be extremely small and unde-

FIG. 4: The reduction in the winding numbers $\langle W_z^2 \rangle$ (proportional to the superfluid density) along the nucleus of the screw dislocation when the ^3He concentration at the dislocation core is increased. The temperature is $T = 0.5\text{K}$ and the density is $n = 0.0295\text{\AA}^{-3}$.

tectable leaving the ^3He contribution as the leading one. Also, binding of ^3He to dislocations has an immediate effect on the shear modulus leading to crystal stiffening at $T < T_{\text{max}}$ as observed in Ref. [10].

Increasing the ^3He concentration in the nucleus of the superfluid screw dislocation is expected to reduce the superfluid density. We assume that ^3He atoms will cluster at the point where dislocations intersect. We model their effect by introducing different numbers of impurities to the dislocation core next to each other (in this simulation we do *not* employ any of the special updates and reweighing mentioned above and thus the ^3He cluster always remains in the core). We see in Fig. 4 that about four ^3He atoms are required to suppress the superfluid response along the core. This mechanism may explain the reduction of the superfluid response for concentrations $x_3 > 1$ ppm observed in Ref. [7].

Our last consideration is about the kinetic relaxation of ^3He atoms. So far we assumed thermodynamic equilibrium which is not necessarily the case. NMR measurements established that the tunneling motion of ^3He atoms in ^4He crystals is characterized by the hopping amplitude $J_{34} \sim 10^{-4} \text{ K}$. Any strain field producing an energy level bias between the nearest neighbor sites $\xi \approx a(dE/dr)$ much larger than zJ_{34} , where z is the coordination number, will localize ^3He atoms. To move around, impurities have to exchange energy with the environment. At low temperatures, the leading mechanism is provided by the one-phonon coupling and leads to hopping rates $\tau^{-1} \sim J_{34}^2 \xi^2 T / \Theta_D^4$ where Θ_D is the Debye temperature [24]. It is clear from the value of the binding energy that in the vicinity of the dislocation core the condition $\xi \gg zJ_{34}$ is definitely satisfied. The slowest rate is for $\xi \sim zJ_{34}$, *i.e.* for ^3He to cross the boundary between the band motion and localized states. One can

see, that the corresponding relaxation time is of the order of years at low temperature leading to sample history dependent effects, as observed in experiments.

In conclusion, we have studied numerically the binding of ^3He to the screw dislocation from first principles. We find a binding energy of $0.8 \pm 0.1\text{K}$ in agreement with published estimates. The binding of ^3He impurity atoms to dislocation cores at low temperature results in a specific heat peak in the same temperature interval as observed experimentally in Ref. [12, 13], and may radically change superfluid properties of the dislocation network even at minute ^3He concentrations. Our data also provide quantitative support to the mechanism proposed in Ref. [10] as an explanation for the crystal stiffening at low temperature.
